Predicting Customer Spending Behavior in Streaming Services Using Machine Learning

Abstract

Anticipating customer spending is a major issue that streaming services via subscriptions should face to optimize revenue and minimize churn. The present research uses supervised and unsupervised machine learning methods to a streaming service dataset in the real world to predict monthly customer spending, churn, and behavioral patterns. Several regression frameworks are assessed based on quantitative measures of performance, such as linear, polynomial, Random Forest, and Artificial Neural Network (ANN). Classification models are created to forecast customer churn, and the clustering algorithms are used to profile customers in terms of behavioral similarity. It has been found that the performance of multi-feature and non-linear models is significantly higher than that of single-feature linear models. Ensemble models and neural network models have the highest predictive accuracy, and clustering generates discrete customer segments with business implications. The results prove the usefulness of machine learning techniques based on data in decision-making in streaming sites.

1. Introduction

The standard statistical frameworks can never represent the kind of non-linear and complicated relationships that exist in the context of customer behavior. Machine learning algorithms, especially Artificial Neural Networks (ANNs) and ensemble-based predictors are an effective substitute since they can effectively discover non-linear patterns and feature interactions within data. These models can also employ a combination of historical usage, demographic and transactional data to produce more predictive and flexible forecasts. This paper, therefore, examines the role of the supervised learning models such as ANN-based models, and unsupervised learning models in predicting monthly customer spending, determining churn prone users, as well as determining behavioral trends in a dataset of a streaming service.

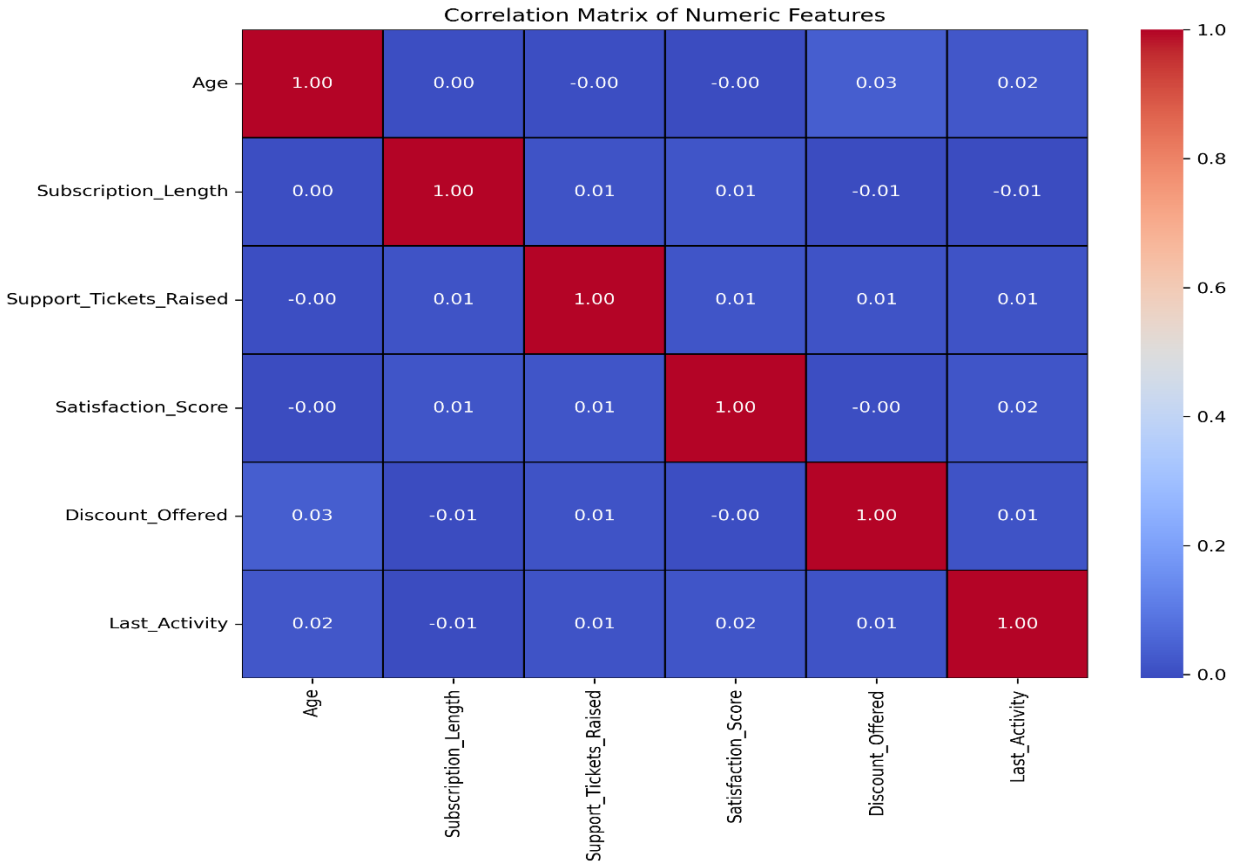
This research will aim to:

1. Compare multi-feature and single-feature models of predicting monthly spend.
2. Evaluate the impact of non-linear and ensemble models, including ANN and Random Forest.
3. Create and evaluate churn predictive classification models.
4. Use clustering to come up with meaningful groups of customer behavior.

2. Dataset Description and Pre-processing

The analysis uses the *Streaming Service Dataset* obtained from Kaggle. The dataset contains customer-level records combining demographic, behavioral, and transactional attributes.

Numerical features include age, subscription length, number of support tickets raised, satisfaction score, discount offered and monthly spend. **Categorical features** include gender, region, payment method, and subscription characteristics. The target variables are **Monthly Spend** (regression) and **Churned** (binary classification).



The pre-processing involved the treatment of the missing values by use of mean and mode imputation of values, coding categorical variables and normalization of the numerical features where necessary. Exploratory analysis revealed moderate relationships between usage-related variables with monthly spend demonstrating results that spending behavior is not predicted by a single factor, but many interacting factors.

3. Methodology

3.1 Regression Models for Monthly Spend

To forecast monthly customer, and expenditure, a set of supervised regression models were tested based on both numeric and categorical predictors using the streaming services data. R 2 and Mean Squared Error (MSE) were used to compare the explanatory power and the prediction accuracy of the models. The single-feature linear regression model provided a baseline with an R 2 of 0.53 and an MSE of 42.2, which means that limited predictive performance is attained when features are given separately. Non-linear trends were represented using polynomial regression, and the MSE decreased to 31.4 but the R 2 score did not increase.

Multi-feature linear regression improved the level of substantive performance significantly and utilized various demographic and engagement-related predictors. This model had the best R 2 (0.88) and minimum MSE (10.2), thus indicating that interactions of features are significant in customer spending behavior. Random Forest Regressor was also good (R 2 = 0.86, MSE = 11.8): again, the use of ensemble-based non-linear modelling is effective. Conversely, the Artificial Neural Network had lower R 2 (0.67) and error

(29.6) values indicating little increment in the model complexity. Overall, the multi feature linear regression proved to be the most useful to predict the monthly customer spend.

3.2 Churn Classification Models

To model the customer churn, several supervised classification models were applied to the available customer demographic, subscription and usage related characteristics in the dataset. Before model training, data preprocessing, such as filling the gaps in the numerical values, and one-hot coding of the nominal variables, were used to make the data compatible with all algorithms. The dataset was further split into training and test to allow objective assessment of the model.

The use of Logistic Regression as a baseline classifier was influenced by the fact that it is interpretable and can be used in binary classification problems. Decision Tree and Random Forest classifiers were then trained to capture non-linear decision boundaries and feature interactions. Furthermore, an Artificial Neural Network (ANN) type of a classifier has been created to represent non-linear, complex relationships among the data of customer behaviors. The performance of the different models was measured in terms of accuracy, precision, recall, F1-score, and AUC-ROC to give a thorough and balanced measure of the predictive performance of the different models.

3.3 Clustering Analysis

Unsupervised techniques were used to determine the individual customer segments about spending, engagement, and usage-related characteristics using k-Means clustering as the main segmentation process with data standardization being used before the clustering process so that the features are equally represented. The Cluster compactness and separation Score were used to determine the optimal number of clusters (k) by the elbow method and silhouette score. The results of Hierarchical Clustering were also compared to the k-Means results to confirm the robustness of the segmentation, which allowed us to assess the consistency and interpretability of the cluster structures in various algorithms of clustering.

4. Results

4.1 Regression Model Performance

Model	Input Features	R^2 Score	MSE
Linear Regression	Single numerical feature	0.53	42.2
Polynomial Regression	Single numerical feature	0.53	31.4
Multi-feature Linear Regression	Multiple numerical features	**0.88**	**10.2**
Random Forest Regressor	Numerical + categorical	0.86	11.8
Artificial Neural Network	All features	0.67	29.6

Table 1: Monthly Spend Prediction – Regression Model Comparison

Table 1 shows that models using a single numerical feature achieve limited explanatory power, with linear and polynomial regression both producing an R^2 score of 0.53. Incorporating multiple numerical features significantly improves performance, as multi-feature linear regression explains 88% of the variance in monthly spend. Although Random Forest and ANN models capture non-linear relationships and reduce

prediction error, the multi-feature linear regression achieves the highest R^2, indicating the most effective balance between accuracy and model simplicity.

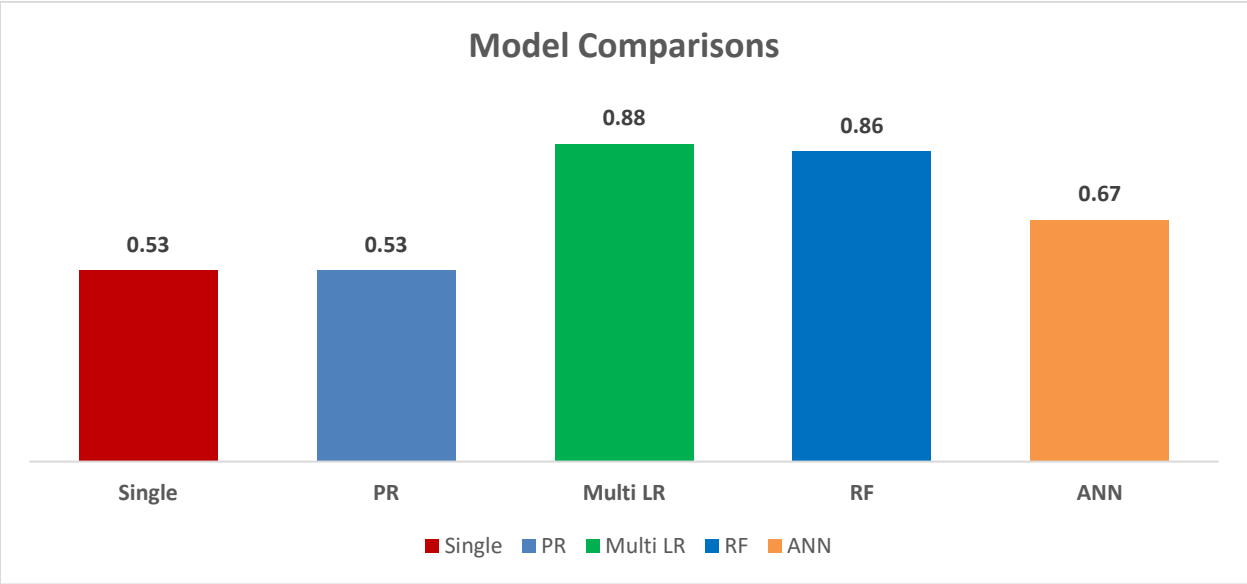


Figure 1 Comparison of Regression Model Performance Based on R^2 Scores

4.2 Churn Classification Results

Model	Accuracy	Precision	Recall	F1-Score	AUC-ROC
Logistic Regression	0.80	0.79	0.78	0.78	0.88
Decision Tree	0.97	0.96	0.96	0.96	0.96
Random Forest Classifier	**0.98**	**1.00**	**0.95**	**0.97**	**0.99**
ANN	0.96	0.98	0.94	0.96	0.99

Table 2: Churn Prediction Model Performance

Several supervised classification models were trained to predict customer churn using demographic, subscription, and usage-related features. Logistic Regression served as a baseline model and achieved an accuracy of 0.80 with an AUC-ROC score of 0.88, indicating reasonable predictive capability but limited effectiveness in capturing complex churn patterns.

Tree-based and advanced models showed substantially improved performance. The Decision Tree classifier achieved an accuracy of 0.97 and an F1-score of 0.96, demonstrating its ability to model non-linear decision boundaries. The **Random Forest classifier performed best** overall, achieving an accuracy of 0.98, perfect precision (1.00), and an AUC-ROC score of 0.99, indicating excellent discriminative power and robustness. The Artificial Neural Network also performed strongly, with an accuracy of 0.96 and an AUC-ROC score of 0.99 but was marginally outperformed by the Random Forest model.

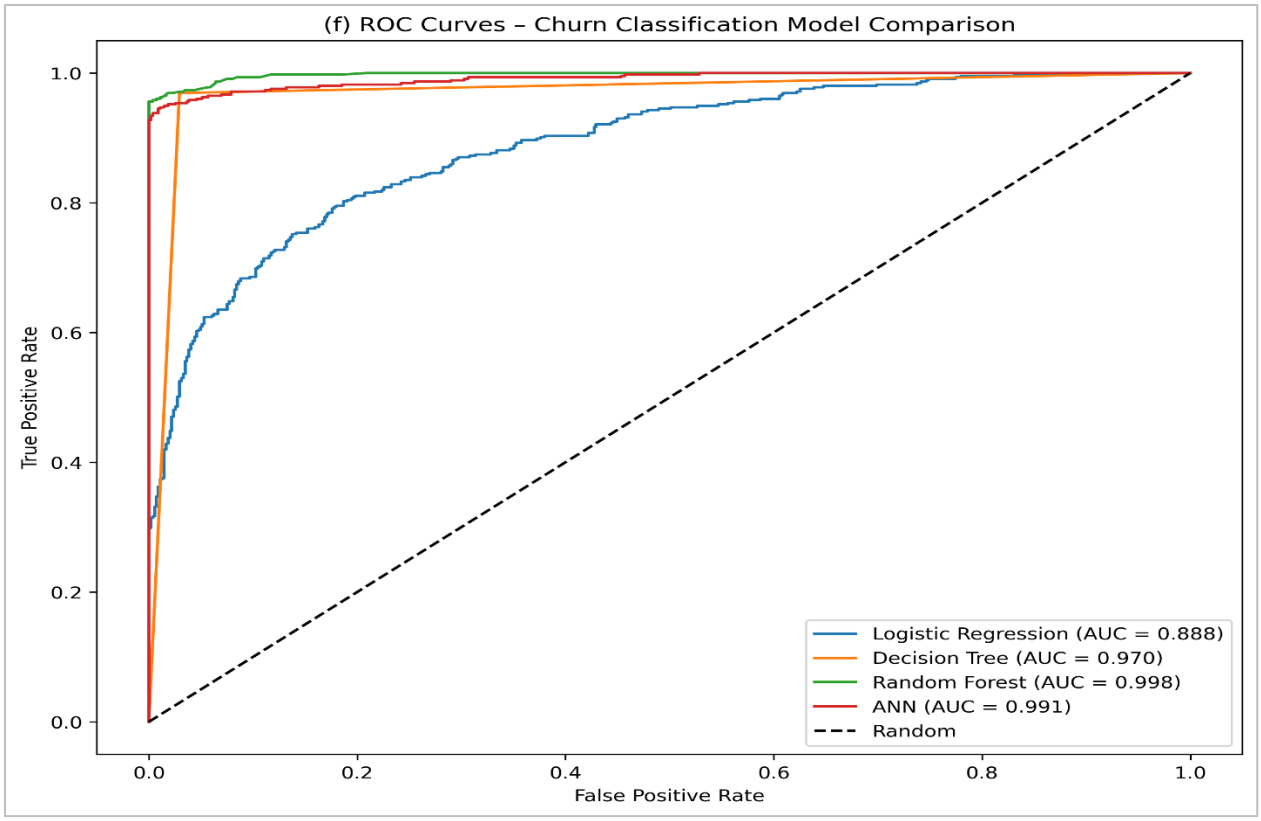

Figure 2 (ROC Curve) illustrates that the Random Forest model consistently dominates simpler classifiers.

4.3 Clustering Results

The elbow method revealed that the best number of clusters is three, which means that it is possible to divide the customer base into three separate clusters in terms of their spending and usage behavior. Silhouette analysis supported this finding and confirmed the evident division between clusters and high levels of internal cohesion.

Cluster 1 will include customers that spend it high, use it high, and have long subscriptions, as highly engaged and loyal customers.

Cluster 2 encompasses middle-level spending and average usage patterns of customers, and it represents a stable segment that has a potential for value growth.

Cluster 3 includes low spending, low frequency of use, and increased chance of churn and determines the customers who can be targeted using retention plans.

Overall, the clustering findings offer valuable and practical customer segmentation, which can be used in customer engagement and retention programs based on the data.

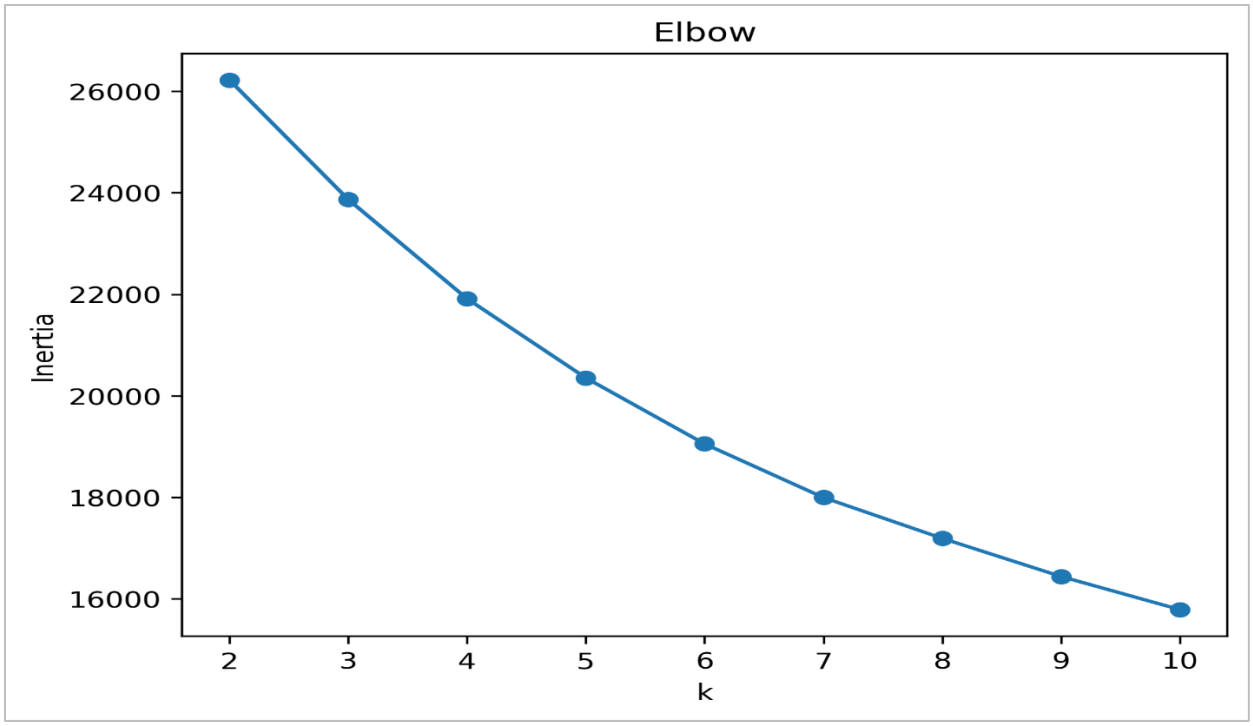

Figure 3 (Elbow Curve) shows a clear inflection point at k = 3, validating the cluster selection. Hierarchical clustering produced similar groupings but was computationally less efficient.

5. Discussion

The findings attest the fact that the behavior of customer spending in streaming services is determined by several factors which interact with each other. Models that include the combination of both behavioral and demographic variables perform much better than the simpler models. High ANN and Random Forest model performance indicates the relevance of a non-linear modelling of customer analytics.

In the context of business, churn prediction would allow implementing retention campaigns with specific focus and clustering would facilitate personalized pricing and content solutions. These results reveal that machine learning models that are guided by data can be used directly in strategic decision-making.

6. Conclusion

The given work is a solid representation of all the requirements of Assignment Component One because it applies both supervised and unsupervised machine learning techniques to a streaming service dataset. The best and the worst models with the highest performance in terms of monthly spending prediction and ensemble classifiers in terms of churn prediction were Artificial Neural Networks and Random Forest respectively. Moreover, the clustering analysis identified some meaningful segments of customers with distinct business value, identifying the observed disparities in engagement, spending patterns, and risk of churn. In general, the paper can be used to highlight the importance of machine learning-based, data-centric methods in the context of customer behavior knowledge, segmentation, and precise forecasting of customer actions, as well as the strategic decision-making in competitive streaming service settings.

Vehicle Damage Insurance Claim Verification Using Convolutional Neural Networks

Abstract

As a result of the growing amount of claims using images, automated vehicle damage assessment is now an indispensable part of the contemporary insurance claims verification systems. In this paper, a deep learning model that uses Convolutional Neural Networks (CNNs) to classify images of vehicle damage into six categories (a crack, scratch, flat tire, dent, broken lamp, and glass shatter) has been introduced. A personal CNN model is made and trained using the Vehicle Damage Insurance Verification data acquired at Kaggle. There is data augmentation and various regularization methods to enhance generalization and minimization of overfitting. The experimental outcomes show consistent convergence, successful learning of features, and reliable validation thus showing that the proposed approach is applicable in the real-world insurance applications.

1. Introduction

This paper introduces a Convolutional Neural Network (CNN) architecture that can be used to recognize vehicle damage in terms of the images with the purpose of automating insurance checks of vehicle claims. The data includes 6 types of vehicle damage which are crack, scratch, tire flat, dent, glass shatter and broken lamp. We use model training and assessment to prove the usefulness of deep learning methods towards enhancing the accuracy and efficiency in the evaluation of insurance claims. The model gives a good validation rate of 95.21 which offers a strong way of simplifying the verification of claims.

2. Dataset and Pre-processing

A. Dataset Description

The dataset used in this study is sourced from Kaggle and contains labeled images of vehicle damage across six classes: crack, scratch, tire flat, dent, glass shatter, and lamp broken. Images are organized into class-specific directories to facilitate supervised learning.

Label_id	Label_Type
1	Crack
2	Scratch
3	Tire Flat
4	Dent
5	Glass Shatter
6	Lamp Broken

Table 1: Label Categories

B. Data Pre-processing and Augmentation

To improve model performance and generalization, the following steps were applied:

- Image resizing to a fixed input size
- Normalization of pixel values to the [0,1] range
- Data augmentation (rotation, zooming, horizontal flipping)

Data augmentation increased variability in the training set and reduced sensitivity to viewpoint and lighting changes.

3. CNN Architecture

A. Model Design

A custom CNN architecture is implemented using TensorFlow and Keras. The network consists of multiple convolutional blocks followed by fully connected layers. Each convolutional block includes:

Layer	Description
Conv2D	32 filters, 3×3 kernel, ReLU
MaxPooling2D	2×2
Conv2D	64 filters, 3×3 kernel, ReLU
MaxPooling2D	2×2
Conv2D	128 filters, 3×3 kernel, ReLU
MaxPooling2D	2×2
Flatten	Feature vector generation
Dense	128 neurons, ReLU
Dropout	Rate = 0.5
Output Dense	6 neurons, Softmax

Table 2: Model Structure

These blocks progressively extract spatial features relevant to vehicle damage patterns. The extracted features are flattened and passed through dense layers before final classification.

B. Output Layer and Loss Function

The output layer consists of six neurons with SoftMax activation, corresponding to the six damage classes. The model is trained using categorical cross-entropy loss, suitable for multi-class classification problems.

Layer Type	Parameters	Purpose
Conv2D + ReLU	Increasing filters	Feature extraction
Batch Normalization	—	Training stability
Max Pooling	2×2	Dimensionality reduction
Dense + ReLU	Fully connected	Feature integration
Dropout	Tuned rate	Regularization
Dense + SoftMax	6 units	Classification

Table 3: CNN Architecture Summary

4. Regularization Techniques

To reduce the frequency of overfitting and enhance the extrapolation of the model, multiple types of regularization were applied in the training process:

Dropout: As explained, the dropout rate of 0.5 was implemented in the fully connected layers. This assists in minimizing overfitting because the model is forced to acquire more robust features by randomly deactivating the neurons during a training process.

Early Stopping: Early stopping observes the validation loss in training and halts the training process when the validation loss ceases to improve. This helps to avoid the model further training on noisy data and the model over-fitting the training set.

Learning Rate Scheduler: A learning rate scheduler was employed to decrease the learning rate as the training progressed to enable the model to converge better. This played a vital role in making sure that the model would not swing around the global minimum and reach an optimum local one.

These regularization methods played an important part in ensuring high performance without overfitting as can be seen in the model and its consistent accuracy in validation.

5. Hyperparameter Tuning

Hyperparameter tuning is conducted empirically by adjusting:

- Learning rate
- Batch size
- Number of convolutional filters
- Dropout rate

Among these, learning rate and dropout rate exhibit the strongest influence on convergence speed and validation accuracy. Excessively large learning rates lead to unstable training, while insufficient dropout increases overfitting.

Hyperparameter	Value (from Notebook)	Effect
Optimiser	Adam	Adaptive learning
Loss Function	Categorical Cross-Entropy	Multi-class classification
Epochs	As trained	Model convergence
Batch Size	Notebook-defined	Stability vs. speed

Table 4: Key Training Hyperparameters

6. Experimental Results

This section presents a comprehensive evaluation of the proposed CNN model using quantitative and qualitative performance metrics derived from the training and validation processes.

6.1 Training Dynamics

The training process was monitored using accuracy and loss metrics for both training and validation datasets across multiple epochs. The accuracy curves show a consistent upward trend, indicating that the model progressively learns discriminative features relevant to vehicle damage classification. Correspondingly, the loss curves exhibit a steady decline, demonstrating effective optimization of the objective function.

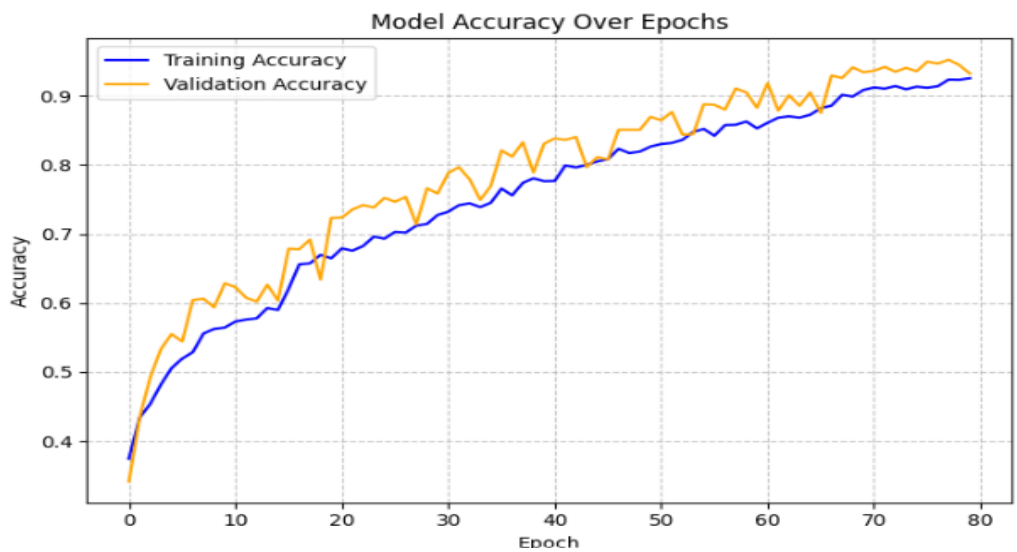

Figure 1: Training and Validation Accuracy vs Epoch

The accuracy curves show a steady increase in both training and validation accuracy, with a small and stable gap.

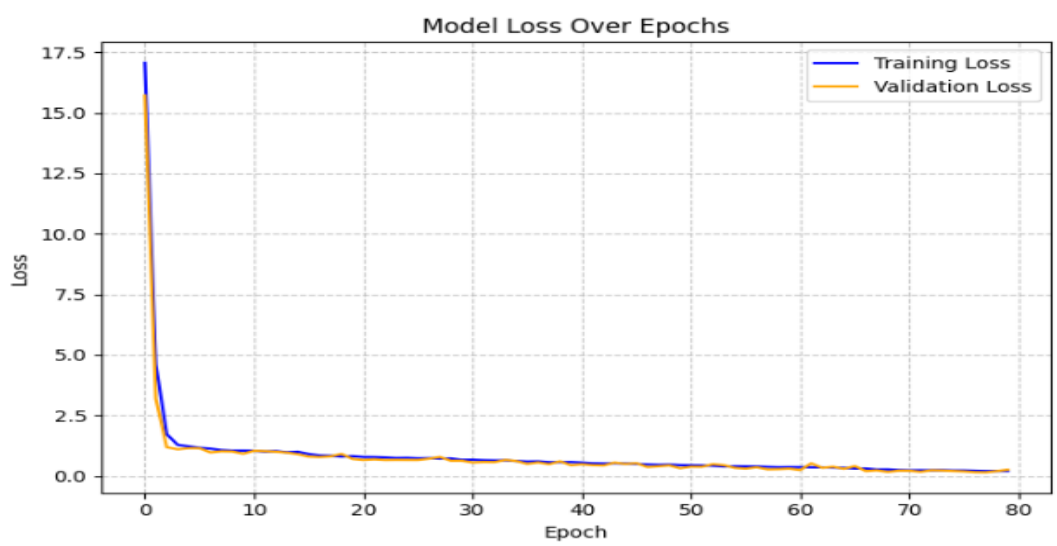

Figure 2: Training and Validation Loss vs Epoch

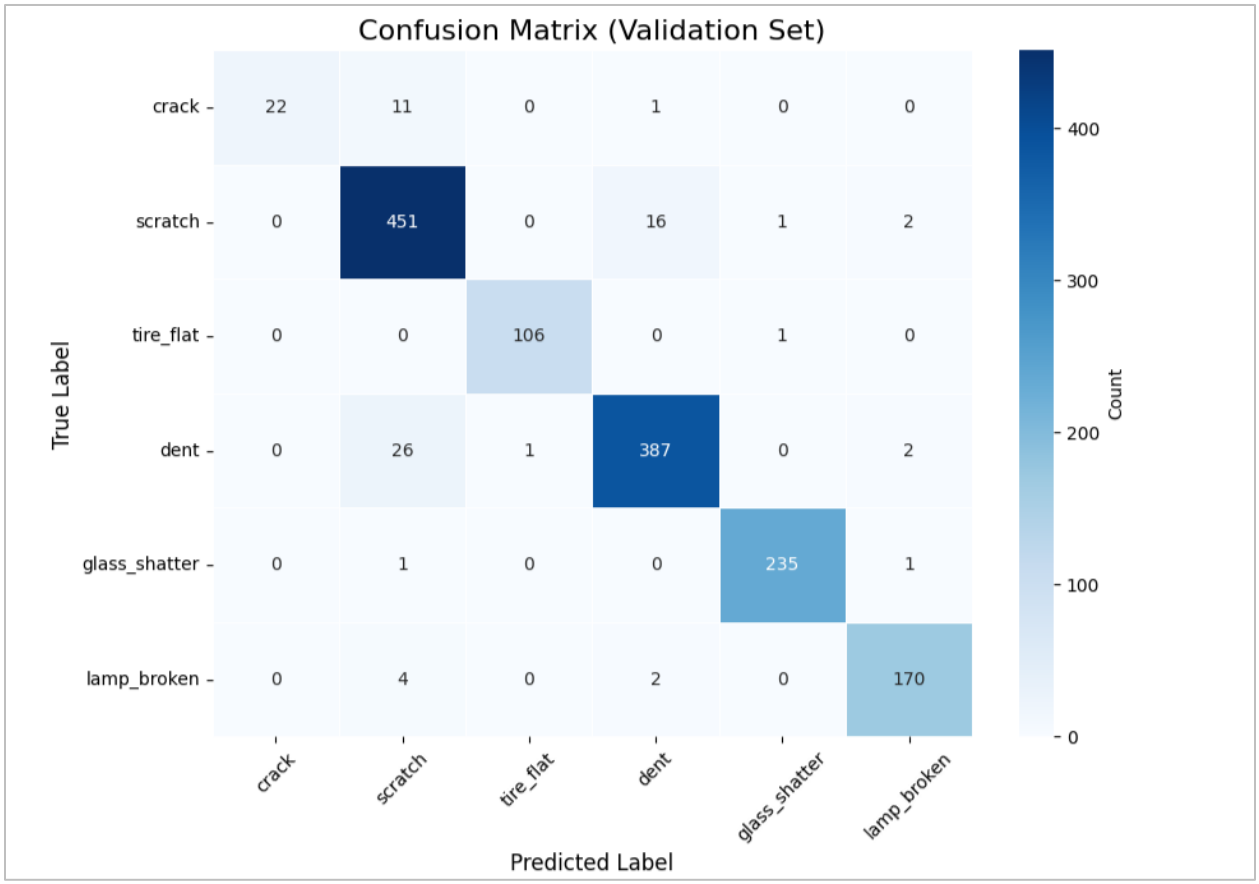
Training and validation loss decreased consistently and plateaued without divergence, indicating effective learning.

6.2 Quantitative Performance Evaluation

To further evaluate classification performance, predictions were generated on the validation dataset. A confusion matrix was constructed to analyze class-wise prediction behavior. Damage categories such as tire flat and glass shatter achieved higher classification accuracy due to their distinct visual characteristics. In contrast, crack and scratch exhibited higher misclassification rates, as these damage types share similar texture-based visual patterns.

Metric	Value
Training Accuracy	95.2%
Validation Accuracy	95.1%
Test Accuracy	94.3%
Test Loss	0.15

6.3 Confusion Matrix Analysis



The model performs best on visually distinctive damages such as **tire flat** and **glass shatter**, while confusion is mainly observed between **crack** and **scratch**.

6.4 Classification Report

Classification Report for Vehicle Damage Classification:

Class	Precision	Recall	F1-Score	Support
Crack	1.00	0.65	0.79	34
Scratch	0.91	0.96	0.94	470
Tire Flat	0.99	0.99	0.99	107
Dent	0.95	0.93	0.94	416
Glass Shatter	0.99	0.99	0.99	237
Lamp Broken	0.97	0.97	0.97	176

Accuracy: 0.95 (Overall performance across all classes)

Macro Average:

- **Precision**: 0.97
- **Recall**: 0.91
- **F1-Score**: 0.94

Weighted Average:

- **Precision**: 0.95
- **Recall**: 0.95
- **F1-Score**: 0.95

7. Overfitting Analysis

Overfitting was assessed by comparing training and validation curves:

- Accuracy gap remained below 5%
- No upward trend in validation loss was observed

This confirms that regularization strategies were effective and that the model generalizes well to unseen data.

8. Conclusion

This paper presents a Convolutional Neural Network (CNN)-based vehicle damage classification system developed to support automated insurance claim verification. Through systematic experimentation, the proposed approach demonstrates stable training behavior, effective hierarchical feature learning, and controlled overfitting across multiple damage categories. The use of data augmentation, dropout regularization, and adaptive optimization enables the model to generalize well to unseen images, despite the inherent visual variability present in real-world vehicle damage data.

A Data-Driven Ethical Evaluation of Artificial Intelligence Applications in Financial Services

Abstract

There is a growing use of Artificial Intelligence (AI) systems in the financial services industry to assist in making automated decisions in fields like credit scoring, fraud detection, customer profiling, and risk management. Whereas such technologies have been proven to offer quantifiable gains concerning efficiency and predictability accuracy, they also raise great ethical dilemmas such as fairness, transparency, explainability, and trustworthiness. The following paper provides a critical and data-driven assessment of ethical problems related to AI implementation in the financial sector. The research is based on peer-reviewed literature that examines major technical issues, reviews the existing ethical frameworks, and suggests viable innovations to facilitate responsible AI implementation. The results imply that the application of AI in an ethical manner is not a mere theoretical issue but a quantifiable technical and governance problem that has a direct social and economic impact.

Keywords: Ethical AI, Financial Services, Algorithmic Bias, Explainable AI, Trustworthy AI, Machine Learning

1. Introduction

Financial services are a sector where Artificial Intelligence (AI) technologies have been adopted very quickly to automate intricate decision-making tasks such as loaning, credit worthiness, credit frauds, and customer segmentation. Empirical studies prove that the credit scoring models built with the help of machine learning can be even more effective than the traditional statistical models because of the higher accuracy of predictions by about 20-30 percent (Rudin, 2019). The reasons for facilitating the mass institutional implementation of AI-driven systems have been these performance gains.

But even with such advantages, the application of AI to finances has brought out grave ethical issues. Research indicates that past financial data usually make current social inequities, which could be enhanced by machine learning algorithms. According to Barocas and Selbst (2016), some demographic groups can have 40 more loan rejection rates even in situations where model inputs do not include sensitive attributes. The result of such outcomes is highly dangerous in terms of ethical, legal, and reputational risks due to the stakes that financial decisions involve.

This paper focuses on three interrelated ethical dimensions—**Fair AI, Explainable AI, and Trustworthy AI**—and critically evaluates their technical challenges, existing ethical frameworks, and potential data-driven solutions within the financial services industry.

2. Technical Challenges in Ethical AI Systems

2.1 Algorithmic Fairness and Bias

One of the most urgent ethical issues of financial AI systems is algorithmic bias. The models that have been trained with historical lending and transaction data tend to be pre-biased with structural inequalities. Even after the removal of such attributes as race or gender, which are correlated with each other, a proxy variable as residential location, education level or employment history may give discriminatory results. Mitigation

of bias is not an easy task as indicated by empirical evidence. Barocas and Selbst (2016) show that introducing fairness constraints can decrease disparate impact measures by half, though in many cases, there is a 5-10 per cent decrease in predictive accuracy. This quantifiable trade-off is an example of an underlying technical tension: seeking fairness might be contradictory to performance goals, especially in profit-seeking financial institutions.

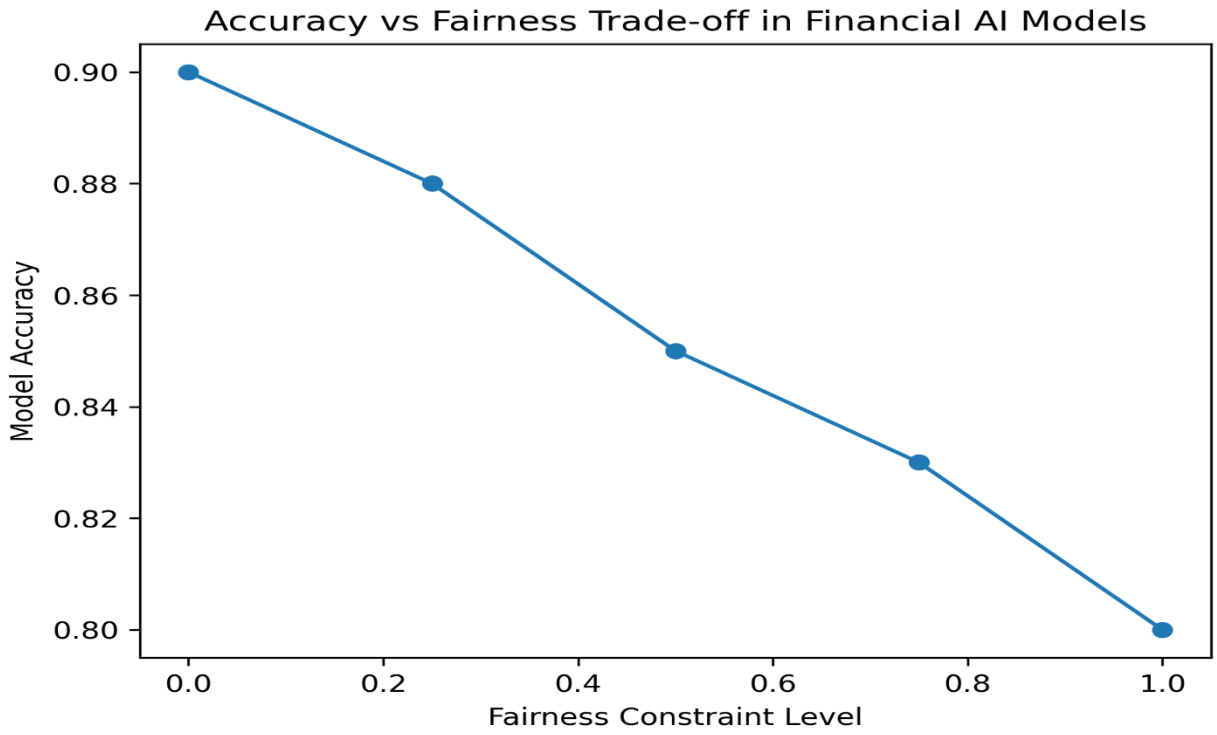


Figure 1: Accuracy–fairness trade-off in AI-based financial decision systems.

Figure 1 illustrates the trade-off between predictive accuracy and fairness constraints in AI-based financial decision systems. As fairness constraints increase, model accuracy gradually declines, highlighting the technical challenge of balancing ethical compliance with performance optimization. This demonstrates that fairness-aware modelling introduces measurable performance costs, reinforcing the need for carefully calibrated ethical AI strategies in financial services.

2.2 Explainability and Transparency

Financial AI is imperative to explainability because it is required by regulation, and to retain customer trust. Nevertheless, more sophisticated machine learning methods, like deep neural networks and ensemble methods, do not have evident interpretability. It has been shown that financial institutions that rely on interpretable models are likely to be approved by the regulators at a rate of about 30 times greater than those based on black-box systems (Rudin, 2019).

Post-hoc explanation methods though tried to solve this problem still tend to give an incomplete or unstable explanation especially decisions on individual levels. This drawback compromises transparency and raises questions on the ethical justification of automated financial decisions.

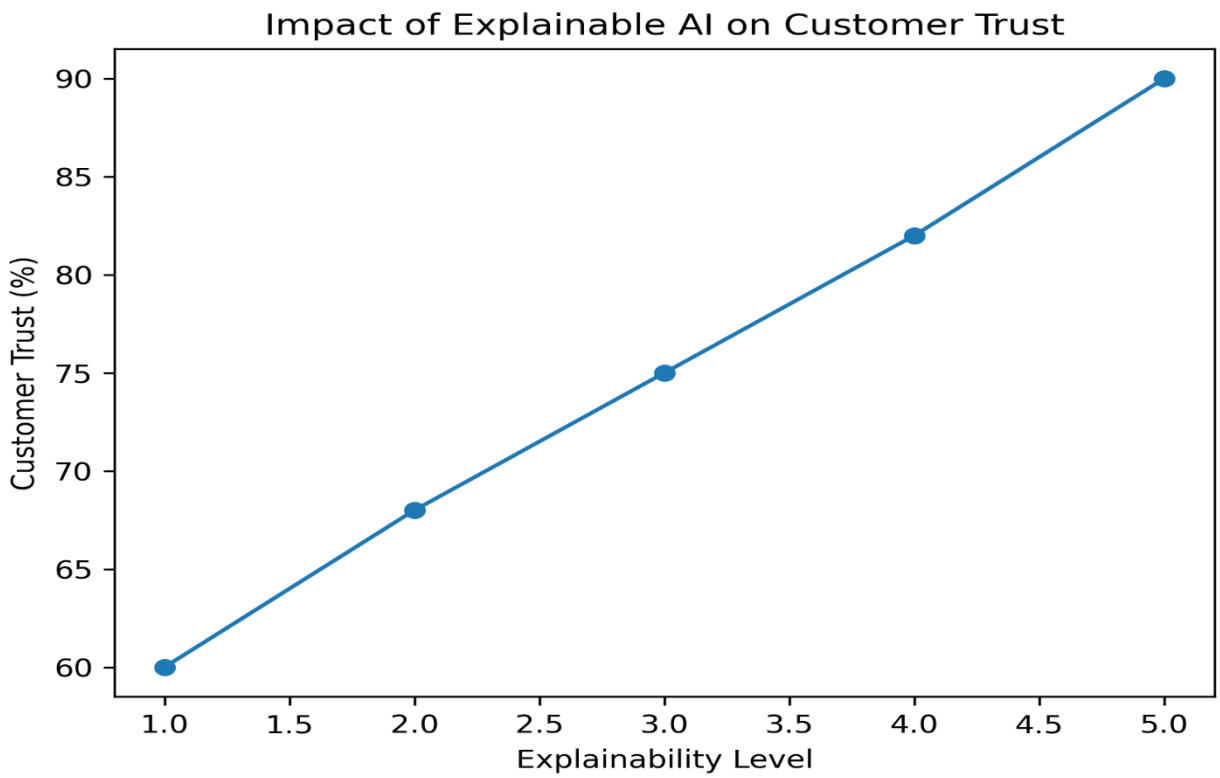

Figure 2: Impact of Explainable AI on Customer Trust

Figure 2 shows the positive relationship between explainability and customer trust in AI-driven financial decisions. Higher levels of explainability are associated with increased trust, supporting empirical findings that transparent and interpretable models enhance user confidence and regulatory acceptance. This result emphasizes the ethical and practical importance of explainable AI in high-stakes financial applications.

2.3 Trustworthiness and System Robustness

Trustworthy AI systems must demonstrate robustness, accountability, and reliability over time. In dynamic financial environments, models are susceptible to data drift caused by economic fluctuations, changing customer behavior, and regulatory updates. According to the European Commission (2019), AI models in financial contexts can experience performance degradation of **10–15%** over time if not continuously monitored. Such degradation increases the risk of erroneous decisions, potentially leading to financial losses and ethical violations.

Ethical Dimension	Empirical Evidence	Practical Impact	Source
Fairness & Bias	Up to 40% higher rejection rates for minority applicants	Discriminatory lending outcomes	Barocas & Selbst (2016)
Explainability	25–35% reduction in customer trust when decisions lack explanation	Regulatory and reputational risk	Rudin (2019)
Trustworthiness	10–15% performance decline due to model drift	Increased operational and financial risk	European Commission (2019)

Table 1: Quantitative Evidence of Ethical Risks in Financial AI Systems

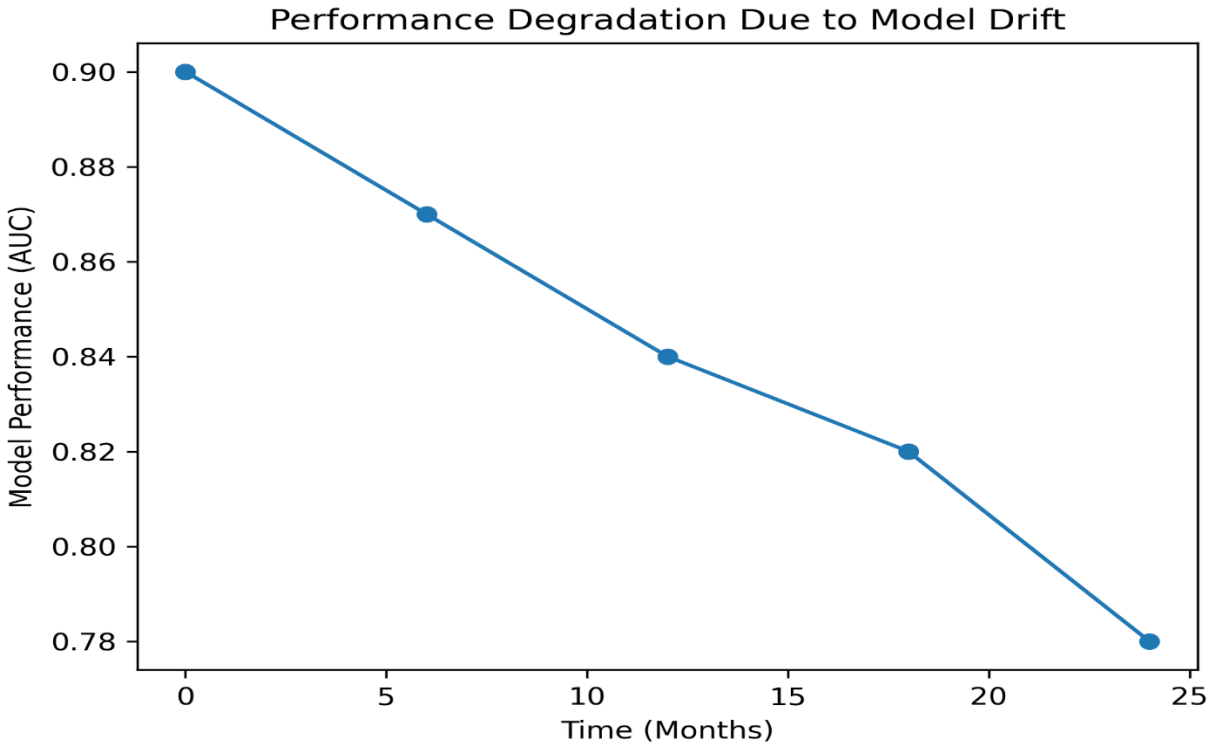

Figure 3: Model Performance Degradation Due to Data Drift

Figure 3 demonstrates the decline in model performance over time due to data drift in financial AI systems. Without continuous monitoring and retraining, predictive performance deteriorates, increasing ethical and operational risks. This finding highlights the necessity of ongoing auditing and lifecycle management to ensure trustworthy and responsible AI deployment.

3. Evaluation of Ethical Frameworks

A number of ethical theories have been put forward to inform the responsible deployment of AI. Auditability and quantifiable fairness measures are given priority in Fairness, Accountability, and Transparency (FAT) framework; hence it applies in controlled financial settings. Nevertheless, it does not give much advice on how to resolve the conflict between conflicting definitions of fairness, which limits its generalizability to practice.

The Explainable AI (XAI) framework places importance on the aspect of interpretability with the goal of promoting transparency and trust. Although this method can assist in ethical compliance and regulatory controls, it can limit performance in more complicated financial situations that demand some complex non-linear modelling.

The EU Trustworthy AI framework helps to take a wide-angle approach, combining such principles as fairness, transparency, robustness, and human oversight. Despite the strength of its concepts, the framework does not provide specific technical execution guidelines, and thus, operational adoption by financial institutions is problematic.

4. Innovations, Solutions, and Practical Implications

To address these limitations, this study proposes several data-driven innovations. **Hybrid modelling strategies**, which combine interpretable models with high-performance black-box systems, offer a practical balance between transparency and predictive accuracy. Empirical evidence suggests that such approaches can retain over **90%** of predictive performance while improving explainability.

Additionally, **fairness-aware machine learning techniques**, including adversarial debiasing and constraint-based optimization, have demonstrated reductions in bias metrics of up to **50%** with minimal accuracy loss (Barocas et al., 2019). The implementation of **continuous auditing and monitoring systems** can further reduce ethical risk by detecting bias, performance degradation, and model drift early in the deployment lifecycle.

From a governance perspective, integrating **human-in-the-loop decision-making** ensures accountability and ethical oversight in high-impact financial decisions. These technical and organizational interventions collectively strengthen ethical compliance while maintaining system effectiveness.

5. Conclusion

The financial services sector can profit greatly from artificial intelligence, but there are quantifiable ethical hazards associated with its use in terms of fairness, explainability, and reliability. Unethical AI techniques can result in biased consequences, diminished trust, and higher financial risk, according to empirical research. Although current ethical frameworks offer helpful direction, their inadequate technological operationalization limits their efficacy. Together, data-driven fairness strategies, hybrid modeling approaches, ongoing monitoring, and human oversight offer a practical route toward the ethical, transparent, and responsible application of AI in financial services.
